54 **IMAGE PROCESSING APPARATUS.**

57 The image processing apparatus prepares calculated image of high quality by effecting calculation in reduced amounts at the time of γ -fitting within short periods of time maintaining high precision. The γ -function is transformed into a linear equation through logarithmic transformation in order to decrease the amount of calculation for γ -fitting, the measured data after the logarithmic transformation are weighted, and disturbance is removed from the measured data to improve precision for γ -fitting. The calculated image data are operated based on a γ -function curve fitted for each of the pixels, and the data are interpolated for those pixels that could not be calculated, in order to obtain smooth calculated image.

FIG. 1

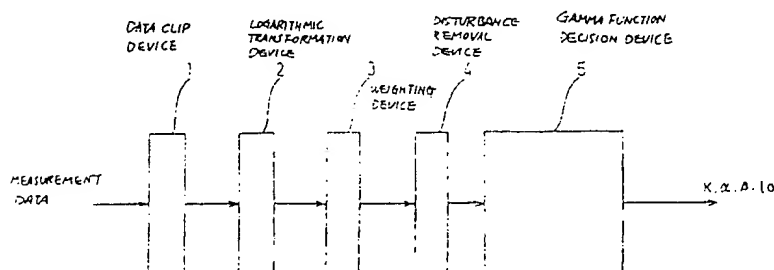

IMAGE PROCESSOR

(Technical Field)

The present invention relates to an image processor in which gamma function curves are set which approximate to curves showing the movement of a contrast medium on a tomogram image taken by a tomograph and various characteristics of the set gamma function curves are constituted as a computer image.

(Background Art)

A tomograph is a device for obtaining a tomogram image of a subject body based on X-ray transmission data obtained by irradiating the subject from its surroundings with X rays. As one of the techniques of tomography there is a method for diagnosis of a morbid part as shown in the following: a water-soluble contrast medium is injected into a vein and an image of a blood vessel or an internal organ, etc. which changes with the lapse of time are observed. The time serial measurement data of a certain point or a part of concern in a tomogram image are said to form a gamma function curve as shown in Fig. 3 when a time axis is taken as the axis of abscissas and the change in a CT number is taken as the axis of ordinates, therefore it is necessary to set a gamma function which approximates most precisely to the measurement data (hereinafter referred to as gamma fitting). In Fig. 3, the points shown with small circles express the data of an identical point on tomogram images obtained in respective times (on respective slices), and they are connected with a gamma function curve 21 which approximates most precisely to the time serial change of the measurement data. The gamma function is expressed in equation (1).

$$f = K (t - t_0)^{\alpha} \exp \{ -\beta (t - t_0) \} \quad \dots (1)$$

As a method for gamma fitting, there is a method in which parameters for making an error minimum is found out asymptotically with a grid search method, etc., or a method in which the gamma function is brought into a normal equation by transforming the gamma function into another function, for example, a logarithmic function. In the former case, that is, in an asymptotic method a great many calculations are needed and moreover the solution can not be always obtained. In the latter case, that is, in a transformation method to a logarithmic function, there are too large errors for practical use in the area where values of data are small. Therefore, it is difficult to perform accurate gamma fitting with a small amount of calculations, and it was not possible to obtain a high quality computer image using the gamma function curves.

(Disclosure of the Invention)

An object of the present invention is to realize an image processor in which an amount of calculation for gamma fitting is decreased, a gamma fitting of high precision is performed in a short time and a computer image of high quality can be formed.

An image processor according to the present invention functions as shown in the following: the amount of calculations for gamma fitting is decreased by transforming a gamma function to a first degree equation through logarithmic transformation; the accuracy of gamma fitting is improved by weighting measurement data transformed to a logarithmic function, and by removing disturbance in the measurement data; a smooth computer image can be formed by operating computer image data from gamma function curves which are fitted to respective picture elements, and by interpolating the data for incalculable picture elements.

(Brief Description of the Drawings)

10 (Most Preferred Configuration for Executing the Invention)

In Fig. 1, 1 is a data clip device which replaces a datum having a negative CT number to that having a positive number close to zero when the time serial measurement data of a certain point or a part of concern on a plurality of tomogram images obtained by slicing in a plurality of times of scans are transformed to the data in a coordinate system which is based on the time and the CT number of the leading data. The data clip device processes input data as shown below. An example of input data is shown in Fig. 4, and the process for the data will be explained. Each point in the figure is plotted based on the data obtained by slicing at each point of time. The numbers attached to the data are data numbers, and data 1 express the data of CT number CT1 obtained at a time T1 in the first slicing, and data i express the data of CT number CTi obtained at a time Ti in the No. i slicing. The data clip 1 transforms the data shown in Fig. 4 for gamma fitting to the data in a coordinate system based on the time T1 and the CT number CT1 of data 1, a leading data, that is, the data just before the arrival of a contrast medium. The coordinate-transformed data are shown in Fig. 5. In the graph shown in Fig. 5, the increment of the CT number of data 2 is negative, so that the data clip device 1 replaces the negative value with a certain value A close to zero which is set beforehand ($A > 0$). The coordinate transformation is, therefore performed as shown in equation (2).

$$(T1, CT1) \longrightarrow (t1, M1') \quad \text{--- (2)}$$

$$\text{where } t1 = T1 - T1$$

$$M1' = CT1 - CT1 \quad (\text{when } CT1 - CT1 \geq A)$$

$$= A \quad (\text{when } CT1 - CT1 < A)$$

A part 2 is a logarithmic transformation device which sustains an expression of a gamma function in equation (1) in the form of a first degree equation being transformed to a logarithmic function, and transforms the output data of the data clip device 1 to a logarithmic function and substitutes them successively for the coefficients in equation (1). The device sustains the expression of gamma function in equation (1) in the form of a three element first degree equation being transformed to a logarithmic function as shown in equation (3).

$$M = ax + by + cz \quad \text{--- (3)}$$

$$\text{where } M = \log . f$$

$$x = \log . K$$

$$y = \alpha$$

$$z = \beta$$

$$a = 1$$

$$b = \log . (t - t_0) \quad (\text{Hereinafter abbreviate } \log e \text{ as } \log)$$

$$c = - (t - t_0)$$

In the data clip device 1, the respective values M_1 , b_1 and c_1 in equation (3) are given by the coordinate-transformed output data (t_1 , M_1'). Therefore, equation (4) is obtained from equation (3). A proper value is applied to it until the value of it is decided later.

$$x + b_1 y + c_1 z - M_1 = 0 \quad \dots (4)$$

A part 3 is a weighting device to make the accuracy of gamma fitting in a logarithmic space equivalent to the accuracy of gamma fitting in a real space. Even if gamma fitting is performed by the output data of the logarithmic transformation device 2, it is a phenomenon in the logarithmic space, and the fitting is largely influenced by the measurement data of small values, therefore the accuracy for approximation in the real space is degraded. The object of the weighting device 3 is to improve the above-mentioned problem. Let e_i be the residual at a measurement point i , when the left side of equation (4) does not become zero. In general for gamma fitting the values of x , y and z which make the square value sum of e_i 's minimum are to be found as shown in equation (5).

$$\sum_{i=1}^n e_i^2 = \sum_{i=1}^n (x + b_1 y + c_1 z - M_1)^2 \quad \dots (5)$$

Since the evaluation of equation (5) is made concerning a logarithmic space, in the present invention to improve the fitting accuracy in a real space, equation (5) is evaluated by a weighting function w_1 , a function of M_1 .

$$\begin{aligned} \sum_{i=1}^n e_i^2 &= \sum_{i=1}^n (w_1 e_i)^2 \\ &= \sum_{i=1}^n \{ (x + b_1 y + c_1 z - M_1) w_1 \}^2 \quad \dots (6) \end{aligned}$$

A lot of things can be considered about the above-mentioned weighting function w_1 , but an example of them will be explained referring to Fig. 6. In comparison with a data set X in a real space, consideration is made on the $\log X$ which is obtained by logarithmic transformation of the data set X . Fig. 6 is a graph showing a curve of $Y = \log X$ corresponding to the data X in a real space. In the figure, let $(X_0, \log X_0)$ be the coordinates of P , then the change sensitivity in the ordinate Y for the change in the abscissa X of data P can be expressed by a differential coefficient $1/X_0$ at point P on the curve $\log X$. Therefore, it is made possible to obtain gamma fitting which is not influenced by nonlinearity generated in logarithmic transformation for an arbitrary data X by multiplying the reciprocal of a differential coefficient by the residual in a logarithmic space. Because of this, in the case of transformation to a logarithmic space, the weighting function $w(X)$ can be decided to be $w(X) = 1/(1/X) = X$. Let w_1 in equation (6) be $w_1 = M_1'$ and let the expression be sustained in the weighting device 3, and by substituting input data t_1 , M_1' successively, the gamma fitting equivalent to that in a real space can be obtained. Therefore, the equation corrected by the weighting function becomes the one just as shown in equation (7).

$$\sum_{i=1}^n e_i^2 = \sum_{i=1}^n \{ (x + b_1 y + c_1 z - M_1) M_1' \}^2 \quad \dots (7)$$

A part 4 is a disturbance removal device for removing data errors in the weighted slice data from the weighting device 3 caused by disturbances such as the ones in which a secondary peak is generated at the trailing edge of a curve or the trailing edge of the curve is blunted as shown in Fig. 7 caused by the influence of blood re-circulation etc. In Fig. 7, $(1, 2, 3, \dots, m, \dots, p, \dots, n)$ are measurement data, and the data $m+1$ are the data of which trailing edge is blunted and data P are the data showing a secondary peak. The curve connecting measurement data shows the curve of a gamma function to be found, and the data m

+ 1, the data P, etc. are regarded to be the data which do not show original correct values because of disturbances. In the disturbance removal device 4, the percentage value RP for a peak value PV which appears in the measurement data is set beforehand. The measurement data m of the slice which fall smaller than (RP/100) x PV (peak value) for the first time will be found and the measurement data m are made to be the final data to be used for gamma fitting. The disturbance removal device 4 transforms equation (7) to equation (8).

$$E = \sum_{i=1}^m \{ (x+b, y+c, z-M_i) M_i' \}^2 \quad \dots (8)$$

where m = final data to be used for gamma fitting

E = square value sum of residual to be evaluated

A part 5 is a gamma function decision device for deciding a gamma function by finding the value of a variable which makes the square value sum E of the residuals in equation (8) obtained in the disturbance removal device 4 minimum. It performs operation as shown below. From equation (8), normal equations are obtained in which partial differential coefficients are put equal to zero as shown in the following.

$$\frac{\partial}{\partial x} E = 0$$

$$\frac{\partial}{\partial y} E = 0$$

$$\frac{\partial}{\partial z} E = 0$$

25

These simultaneous equations are expressed as shown in equation (9).

$$AX = B \quad \dots (9)$$

30

Besides x, y and z, another parameter t0 (refer to equation (3)) has to be decided to solve equation (9). For this purpose, in the device according to the present embodiment, the values of t0 of several kinds to several tens of kinds, which are selected as explained later, are substituted for b1 and c1 in equation (8), and equation (9) is solved independently for respective values of t0; in the result, a gamma function is decided from K, α , β and t0 which make the square value sum E of the residuals minimum among all solutions for gamma fitting. How to select the several kinds to several tens of kinds of t0 values is shown in Fig. 8. A percentage value AP of measurement data for a peak value PV, and the number of times of repetition of fitting N are set beforehand. The measurement data (circle marks in the graph) of each slice are compared with the value (AP/100) x PV to find out a first slice of which measurement data become higher than (AP/100) x PV, and let T be the time of it. Let t0 be a value selected in the following equation and the gamma fitting of N times is performed.

$$t_0 = \Delta T \times j$$

where $\Delta T = T/N$,

$$j = 0, 1, 2, \dots, N-1$$

45

In the result of gamma fitting of N times, a gamma function in which E becomes minimum is decided to be the one to be found.

The t0 decided as described above is positioned as shown in Fig. 8. Let 1 be a slice right after t0, then the data of slices before 1 - 1 are not used. They are not used for gamma fitting, however, they are used for the evaluation of the square value sum E of the residuals as shown in equation (10) to be able to perform correct evaluation for any t0.

$$E = \sum_{i=1}^{l-1} M_i^2 + \sum_{i=l}^m \{ (x+b, y+c, z-M_i) M_i' \}^2 \quad \dots (10)$$

55

In equation (10), the first term on the right side shows the slice data which are not used for gamma fitting, and the second term shows the slice data which are used for gamma fitting and the slice data from 1 to m are reflected in equation (9). The gamma function decision device 5, as described above, solves a normal equation in equation (9) for t_0 's of N times, and a gamma function to be found is decided by K, α , β , and t_0 when the square value sum E of the residuals become minimum.

A gamma fitting device as described above has advantages as shown in the following.

(1) Calculation quantity is decreased much and calculation time is shortened much in performing least square approximation by solving normal equations obtained through logarithmic transformation of measurement quantities.

(2) The gamma fitting equivalent to the gamma fitting in a real space can be performed by performing weighting in a logarithmic space, which makes it possible to improve the accuracy of gamma fitting.

(3) It becomes possible to perform accurate gamma fitting by original data by realizing the removal of disturbance.

(4) An optimum starting time of gamma fitting can be automatically decided by the decision method of t_0 and the evaluation by equation (10).

A gamma fitting device is not limited to the above-mentioned embodiment. In the embodiment, explanation is given about the data, time and the increment of a CT number, however an arbitrary time serial data can be approximated by a gamma function. As an example of a weighting function, $w(X) = X$ is adopted but another weighting function can be used.

An image processor using the gamma fitting device as mentioned above is constituted as shown in Fig. 2. In Fig. 2, 11 is the gamma fitting device which performs gamma fitting operation for each picture element of the picture element data of each tomograph image obtained in each slicing, and decides a gamma function which approximates most precisely to the time serial change of the picture data. A part 12 is a data control device which controls the gamma fitting device 11 to perform the operation for finding a gamma function fitted for respective picture element data based on the input data of scanned images; in the result, all the sets of parameters K, α , β , and t_0 which express gamma function curves of respective picture element data obtained from the gamma fitting device 11 are stored in the data control device by picture elements; and after that gamma function curves are reproduced by the above-mentioned parameters K, α , β , and t_0 , and various kinds of computer image data such as a peak value and an area below a gamma function curve, to be described later, are operated. In the operation process of computer images as described in the above, if an excessive numerical value is generated and a picture element which may overflow is found, the operation will be suspended and a mark of operation suspension is stored in place of the picture element data. A part 13 is an interpolation device, and when it finds a mark of operation suspension in the input data from the data control device 12, re-search of image data is performed over the range of $N \times N$ matrix centering the picture element, and when there are found more than M effective data in the matrix of $N \times N$, an average value of these effective data will be substituted for the mark of operation suspension to fill data blank, and when picture element data are completed, a computer image constituted by the data control device 12 is supplemented to be completed. By this arrangement, it is made possible to supplement smoothly the value of an incalculable picture element caused by overflow, etc. by interpolation from the circumference and to obtain a computer image of good picture quality and good to look at. A computer image output from the interpolation device is displayed in a display device (not shown in the drawing). The matrix size N and the number of data M shall be decided properly depending on the place of observation or the degree of a morbid state. The data control device 12 calculates various kinds of computer images, for example, as shown in the following which are specified beforehand based on the gamma fitting performed by the gamma fitting device 11.

- (1) A peak value of a gamma function curve
- (2) A period of time from the origin of the coordinate to the peak value
- (3) An area below a curve
- (4) Inflection point width
- (5) Time of appearance
- (6) Mean passage time
- (7) Corrected mean passage time
- (8) Relative flow rate

The operation is suspended for a picture element of which overflow is brought about in the process of above-mentioned operation of computer images, and a mark expressing the suspension is given to the picture element. When the interpolation device 13 finds the mark, it tries to obtain an average value of more than M effective data out of $N \times N$ data in the vicinity of the mark for interpolation, and completes the operation of a computer image of which the operation is not completed including the interpolated data to

display the image in a display device.

The explanation on a most preferred form for the execution of the present invention is given as described in the above, however it will be easy to make various transformation without departing from the range of the following claims for the persons having ordinary knowledge in the technical field to which the present invention belongs.

Claims

1. An image processor provided with a gamma fitting means for setting a gamma function curve approximating to a curve showing the movement of a contrast medium in a tomogram image obtained by a tomograph and for constituting various characteristics of the set gamma function curve as a computer image comprising: a data clip means for performing coordinate transformation making the leading data of measurement of an image changing with the lapse of time accompanying the injection of a contrast medium be the origin of the coordinate, and for shifting the data being made to negative data by the coordinate transformation to positive data; a logarithmic transformation means for storing a 3 element first degree equation, a gamma function undergone logarithmic transformation, and for substituting the data from said data clip means for the coefficients; a weighting means for weighting the output data of the logarithmic transformation means; a disturbance removal means for removing disturbance data to correct the disorder of a curve caused by disturbances; and a function decision means for setting an approximate gamma function curve by obtaining unknown parameters of a gamma function by operation based on the data after removal of disturbance from said disturbance removal means.
2. An image processor for setting a gamma function curve approximating to a curve showing the movement of a contrast medium in a tomogram image obtained by a tomograph, and for constituting various characteristics of the set gamma function curve to a computer image comprising: a data clip means for performing coordinate transformation making the leading data of measurement of an image changing with the lapse of time accompanying the injection of a contrast medium be the origin of the coordinate, and for shifting the data made to negative data by coordinate transformation to positive data; a logarithmic transformation means for storing a 3 element first degree equation, a gamma function undergone logarithmic transformation, and for substituting the data from said data clip means for the coefficients; a weighting means for weighting the output data of the logarithmic transformation means; a disturbance removal means for removing disturbance data to correct the disorder of a curve caused by disturbances; a gamma fitting means comprising a gamma function decision means for setting an approximate gamma function curve by obtaining unknown parameters of a gamma function by operation based on the data after removal of disturbances from said disturbance removal means; a data control means for forming a computer image based on a gamma function curve obtained by the calculation of gamma function decision parameters output from said fitting means by controlling the operation of said gamma fitting means; and an interpolation means for completing a computer image by interpolating the picture elements in an incalculable part in the operation process by said data control means.

Description

This invention relates to a method for generating a representation of an image, in particular where the input image is scanned from a film.

When an image is captured on film with normal exposure there will be a difference in appearance between the actual scene and the image, caused by the characteristic response of film. The effect of this is generally an expansion of detail in the midtones and compression of detail in highlight and lowlight regions. For a normally exposed scene the distortion is not large and in most cases it will be considered a reasonable reproduction. However for images with high lowlight and highlight content, the distortion becomes obvious and requires correction. Similarly an incorrectly exposed image will suffer distortion which needs to be corrected.

US-A-4849775 describes colour correction for a thermal printing system in which image data from a source, including from a document scanner, is corrected by deriving a correction curve. This is derived from the relationship between the gradations of the image data and optical density values from a grey scale chart. The derived curve is such that the optical density values and corrected gradations are linearly related.

US-A-4866513 describes deriving a gamma value to correct RGB signals from the average, maximum and minimum values of each colour signal within a single frame according to the characteristic values detected.

Rundfunktechnische Mitteilungen, Vol. 26, No 1, pp. 1-9, describes electronic adaptation of parameters for applying film in television including correction of transfer characteristic.

In accordance with the present invention a method of generating a representation of an image comprises scanning a film carrying an image to which the film has been exposed, and wherein during exposure the appearance of the image has been modified in accordance with a characteristic function of the film; obtaining signals representing the colour component content of the image recorded on the film; modifying the signals with a function constituting the inverse of the characteristic function of the film to produce a compensated image; and subsequently applying a chosen film characteristic function to the compensated image.

The application of an inverse film characteristic function to the image removes the effects of the film so that a more accurate representation of the original image is obtained. It is a simpler method than has previously been obtained, yet provides more exact compensation. This method is equally applicable to scanning colour and monochrome films. In the case of a colour film characteristic functions exist for each colour which may differ from each other, but in combination produce a characteristic function of the film.

In accordance with a second aspect of the present invention, apparatus for generating a representation of an image comprises scanning means to scan a film carrying

an image to obtain signals representing the colour component content of the image recorded on the film; modifying means to modify the signals with a function constituting the inverse of a film characteristic function to produce a compensated image; and means for subsequently applying a chosen film characteristic function to the compensated image.

Preferably the modifying means comprise a log amplifier and the signals are converted to density signals.

An example of a method of generating a representation of an image in accordance with the present invention will now be described with reference to the accompanying drawings in which:

Figure 1 shows a density/exposure graph for a typical daylight colour film;

Figure 2 is a graph showing the relationship of the density of the exposed film to the exposure of the original scene;

Figure 3 shows a block diagram of the apparatus used in compensating the scanned image;

Figure 4 shows graphically the effect of applying an inverse characteristic function; and

Figure 5 is a graph relating density of the film after characteristic correction to exposure.

When an image is read into an electronic scanning system, two points are chosen within the image that represent the reference white and black points. These are termed, enter white - EW and enter black - EB. These values are used to define the range of densities over which the information of interest is distributed. The reasons for this representation are firstly it is not always possible to reference the zero of the density axis to be the value of the EW point. This arises from being required to calibrate the measuring device initially with no film being present. When the film is introduced, the density of the substrate must be taken into account, resulting in an offset for the EW from the calibrated zero density. Secondly the dynamic range for various film categories may vary. This results in different separations for the EW and EB values for different film categories. Films may undergo different changes of density range in mid-tone and tail regions. If it is a common film, it results in an expansion of mid-tones and compression of highlight and lowlight details.

The midtone region undergoes an expansion of density range while the lowlight and highlight regions are compressed. The Enter White and Enter Black points are the white and dark points in an image. These represent the range of exposure for a normal scene. Joining the EW and EB points (Figure 1) is a dashed line representing the film characteristic seen by scanners where no account of the shape of the film characteristic is made. The

difference between the dashed line and the film characteristic curve is the distortion observed in an image when compared to the original scene.

Where the image is incorrectly exposed there will be greater distortion effects. This is shown in Figure 2 where the exposure is varied in one stop steps either side of normal exposure. It can be seen that although the original scene exposures have equal increments and range, their respective film densities are irregular. Large distortions are introduced in the lowlight regions for under exposed images and similar distortions in the highlight regions of over exposed images. If the exposure is too extreme, density levels will merge with the extremes of the curve, and will not be recoverable subsequently. The dashed line indicates an example of this where some lowlight values are merged and information content lost. The effect of this is that there are problems in recovering information from images which are either incorrectly exposed or which contain important information near the EW and EB points.

To compensate for these problems a system as shown in Figure 3 is used to apply an inverse characteristic to produce a linear output corresponding to the density profile of the original scene. A light source 1 illuminates a film transparency 2 carrying an image to enable a scanning system 3 of conventional form to scan the image on the transparency 2. The colour component content of the image is divided into red green and blue signals 4,5,6 by the scanning system 3 which are input to a log amplifier 7. The log amplifier 7 converts the signals from the imaging system 3 into density signals. The red, green and blue density signals address respective look-up tables 11,10,8 which store the inverse film characteristic function for each colour. Modified values representing compensated image are output 9 from the look-up table.

It can be seen from Figure 4 that the original scene is substantially unaffected as a result of the film characteristic function because it has been compensated by the inverse film characteristic function. In Figure 5 the graph shows the effect of straightening the characteristic of the curve to a 45° line is to keep the input range and output range the same for all different exposures.

Generally the method described substantially compensates for the effect of the film characteristic function, but in some cases where image information is at the extremes of the characteristic function (eg Figure 4) complete compensation is not achieved. In this Figure the extremes, which are flat, correspond to the film becoming completely clear at the highlight end and receiving less light than required to activate the film at the lowlight end.

If the EW and/or EB points fall within the flattened regions, any density variation within the original scene would be recorded with the same density. It is not possible to recover the information subsequently that was in the original scene from these areas and there will therefore be some distortion.

Once the effect of the film characteristic is removed, it is possible to apply any chosen film characteristic by application of a new film characteristic function to the compensated output. By adding an offset to the values any exposure may be introduced. Most films within a characteristic set have very similar characteristic functions. The curves in the preceding Figures are typical of all daylight colour films. Each of the three colour channels, red, green and blue have their own characteristic curve. Due to variations in the film from each batch produced, it is only possible to produce an average for these curves. The data for the shape of these curves is normally published by film manufactures, but may also be determined by performing some controlled exposure tests.

A characteristic set for example, is a set of films that have "film characteristics" that are very similar. This occurs because films from different manufacturers use similar technology and also try to make specific films such that their responses are predictable under similar circumstances.

Claims

1. A method of generating a representation of an image, the method comprising scanning a film (2) carrying an image to which the film has been exposed, and wherein during exposure the appearance of the image has been modified in accordance with a characteristic function of the film; obtaining signals (4,5,6) representing the colour component content of the image recorded on the film; modifying the signals with a function (11,10,8) constituting the inverse of the characteristic function of the film to produce a compensated image; and subsequently applying a chosen film characteristic function to the compensated image.
2. A method according to claim 1, wherein the scanned film (2) is a colour film.
3. Apparatus for generating a representation of an image (2) comprising scanning means (3) to scan a film (2) carrying an image to obtain signals (4,5,6) representing the colour component content of the image recorded on the film; modifying means (7) to modify the signals with a function (11,10,8) constituting the inverse of a film characteristic function to produce a compensated image; and means for subsequently applying a chosen film characteristic function to the compensated image.
4. Apparatus according to claim 3 wherein the modifying means comprise a log amplifier (7) and wherein the signals are converted to density signals.

Patentansprüche

1. Verfahren zum Erzeugen einer Bilddarstellung, bei dem ein Film (2) abgetastet wird, der ein durch Belichtung des Films entstandenes Bild trägt, und mit dem während der Belichtung das Aussehen des Bildes entsprechend einer charakteristischen Funktion des Films modifiziert worden ist, bei dem den Farbkomponenteninhalt des Filmbildes darstellende Signale (4, 5, 6) erzeugt werden, die Signale mit einer Funktion (11, 10, 8) modifiziert werden, welche invers zur charakteristischen Funktion des Films sind, um ein kompensiertes Bild zu erzeugen, und bei dem anschließend das kompensierte Bild entsprechend einer gewählten filmcharakteristischen Funktion verändert wird.
2. Verfahren nach Anspruch 1, bei dem der abgetastete Film (2) ein Farbfilm ist.
3. Vorrichtung zum Erzeugen einer Bilddarstellung (2) mit Abtastmitteln (3) zum Abtasten eines Filmes (2), der ein Bild aufweist, um den Farbkomponenteninhalt des auf dem Film aufgezeichneten Bildes darstellende Signale (4, 5, 6) zu erzeugen, mit Modifizierungsmitteln (7) zum Modifizieren der Signale mit einer Funktion (11, 10, 8), die invers zu einer filmcharakteristischen Funktion ist, um ein kompensiertes Bild zu erzeugen, und mit Mitteln zum anschließenden Einwirken auf das kompensierte Bild mit einer gewählten filmcharakteristischen Funktion.
4. Vorrichtung nach Anspruch 3, bei der die Modifizierungsmittel einen logarithmischen Verstärker (7) aufweisen, und bei dem die Signale in Dichtesignale umgewandelt werden.

d'une image (2), comportant des moyens de balayage (3) pour balayer un film (2) portant une image en vue d'obtenir des signaux (4, 5, 6) représentant le contenu en composantes de couleurs de l'image enregistrée sur le film; des moyens de modification (7) pour modifier les signaux par une fonction (11, 10, 8) constituant l'inverse d'une fonction caractéristique du film pour produire une image compensée; et des moyens pour appliquer ensuite à l'image compensée une fonction caractéristique de film choisie.

4. Appareil selon la revendication 3, dans lequel les moyens de modification comportent un amplificateur logarithmique (7), et dans lequel les signaux sont convertis en signaux de densité.

Revendications

1. Procédé pour la restitution d'une représentation d'une image, le procédé comportant le balayage d'un film (2) portant une image avec laquelle le film a été exposé, et dans lequel l'aspect de l'image a été modifié au cours de l'exposition selon une fonction caractéristique du film; l'obtention de signaux (4, 5, 6) représentant le contenu en composantes de couleurs de l'image enregistrée sur le film; la modification des signaux par une fonction (11, 10, 8) constituant l'inverse de la fonction caractéristique du film pour produire une image compensée; et ensuite l'application à l'image compensée d'une fonction caractéristique de film choisie.
2. Procédé selon la revendication 1, dans lequel le film balayé (2) est un film couleur.
3. Appareil pour la restitution d'une représentation
